Abstract
In type theory, programming and reasoning with possibly non-terminating programs and potentially
infinite objects is achieved using coinductive types. Recursively defined programs of these types need
to be productive to guarantee the consistency of the type system. Proof assistants such as Agda
and Coq traditionally employ strict syntactic productivity checks, which often make programming
with coinductive types convoluted. One way to overcome this issue is by encoding productivity at
the level of types so that the type system forbids the implementation of non-productive corecursive
programs. In this paper we compare two different approaches to type-based productivity: guarded
recursion and sized types. More specifically, we show how to simulate guarded recursion in Agda
using sized types. We formalize the syntax of a simple type theory for guarded recursion, which is a
variant of Atkey and McBride’s calculus for productive coprogramming. Then we give a denotational
semantics using presheaves over the preorder of sizes. Sized types are fundamentally used to interpret
the characteristic features of guarded recursion, notably the fixpoint combinator.

1 Introduction

Dependent type theory is an expressive functional programming language that underlies the
deductive system of proof assistants such as Agda [22] and Coq [10]. It is a total language,
meaning that every program definable inside type theory is necessarily terminating. This is
an important requirement that ensures the consistency of the type system.

Possibly non-terminating computations and infinite structures, such as non-wellfounded
trees, can be represented in type theory by extending the type system with coinductive
types. Recursively defined elements of these types need to be productive in the sense that
every finite part of the output can be computed in a finite number of steps [15]. In Agda’s
encoding of coinductive types using “musical notation” [16], productivity is enforced via
a strict obligation: in the definition of a corecursive function, recursive calls must appear
directly under the application of a constructor. A similar syntactic check is used in Coq. This
restriction typically makes programming with coinductive types cumbersome, which spawned
the search for alternative techniques to ensure the well-definedness of corecursive definitions.
We focus on two of these techniques in which productivity is encoded at the level of types: sized types and guarded recursion. A sized type is a type annotated with the number of unfoldings that elements of this type can undergo [17]. Sized types have been implemented in Agda and can be used in combination with coinductive records to specify coinductive types [4, 6], as exemplified by Abel and Chapman’s work [3]. There also are other approaches to sized types. One of those is developed by Sacchini [23], which allows less terms to be typed compared to Agda’s approach.

Guarded recursion [21] is a different approach where the type system is enhanced with a modality, called “later” and written ⊥, encoding time delay in types. The later modality comes with a general fixpoint combinator for programming with productive recursive functions and allows the specification of guarded recursive types. These types can be used in combination with clock quantification to define coinductive types [8, 9, 12]. Currently there is no implementation of a calculus for guarded recursion.

Sized types and guarded recursion are different solutions to the same problem, but a thorough study of the relation between these two disciplines is still missing. In this paper we take a first step in this direction by showing how guarded recursion can be simulated in Agda using sized types.

Utilizing techniques for representing “type theory in type theory” [7, 13], we present an Agda formalization of the syntax of a simple type theory for guarded recursion. This object language, which we call GTT, is a variant of Atkey and McBride’s type system for productive coprogramming [8] in which the clock context can contain at most one clock. The types of GTT include the aforementioned ⊥ modality and a □ modality, a nameless analogue of Atkey and McBride’s universal clock quantification. Clouston et al. [14] studied a guarded variant of lambda calculus extended with a □ operation, which they call “constant”. Our object calculus differs from theirs in that our judgments are indexed by a clock context, which can be empty or containing exactly one clock. The design of GTT has the benefit of allowing a more appealing introduction rule for □ than Clouston et al.’s. GTT also differs from Clouston et al.’s calculus in the class of definable guarded recursive types. We follow Atkey and McBride’s approach and restrict the least fixpoint operator µ to act on strictly positive functors, while µ type former in Clouston et al.so only operates on functors in which all variables are guarded by an occurrence of the ⊥ modality.

 Afterwards we develop a categorical semantics for GTT using sized types. More precisely, we define a presheaf model where the type formers of simply typed lambda calculus are evaluated using the standard Kripke semantics. Typically, the semantics of a type theory for guarded recursion is given in the topos of trees or variations thereof [11, 19, 20]. Here, to clarify the connection between guarded recursion and sized types, we take the preorder of sizes as the indexing category of our presheaves. This means that types and contexts of GTT are interpreted as antitone sized types. The well-order relation on sizes is fundamental for constructing a terminating definition of the semantic fixpoint combinator.

The decision to restrict the clock context of GTT to contain at most one clock variable was dictated by our choice to use Agda with sized types as the metatheory. In Agda, it is possible to encode semantic clock contexts containing multiple clocks as lists of sizes or as functions from a finite interval of natural numbers into sizes. However, Agda’s support for sized types is tailored to types depending on exactly one size, or on a finite but precise number of sizes, which makes it cumbersome to work with types depending on clock contexts containing an indefinite number of clocks. More technically, as it was privately communicated to us by Agda implementors, Agda’s type inference only works properly for first-order size constraints. We believe that if future Agda releases add the capability of handling multiple
sizes, it would be possible to extend the semantics of GTT to include the full Atkey and McBride’s type theory. We also believe that extending our formalization to the multiclock case, while technically challenging, would not be conceptually harder.

GTT is strictly less expressive than Atkey and McBride’s calculus, since we are unable to implement nested coinductive types. But the one clock variant of the calculus still allows the construction of a large class of coinductive types and it is the subject of active research [14].

To summarize, the contributions of this paper are twofold:

1. We formalize syntax and semantics of a type theory for guarded recursion in Agda. This is the first such denotational model developed using an extension of Martin-Löf intensional type theory as the metalanguage, in contrast with the previous set-theoretic models of guarded recursion.
2. The interpretation of the characteristic features of guarded recursion crucially requires the employment of sized types. This shows that guarded recursion can be reduced to sized types and constitutes a stepping stone towards a clear understanding of the connections between different approaches to productive coprogramming.

This paper only include the essential parts of our Agda formalization. The full code is available at https://github.com/niccoloveltri/agda-gtt. The formalization uses Agda 2.5.4.2 and Agda standard library 0.16. The paper is extracted from a literate Agda file, which implies that all the displayed code passed Agda’s type and termination checker.

The material is organized in the following way. In Section 2, we discuss the metatheory and we give an overview of sized types. In Section 3, we introduce the syntax of GTT, our object type theory for guarded recursion. Subsequently, we give a categorical semantics. In Section 4, we show how to implement presheaves over sizes and how to model the fragment of GTT corresponding to simply typed lambda calculus. In Section 5, we discuss the semantics of the guarded recursive and coinductive features. In Section 6, we prove the object language sound w.r.t. the categorical model, which in turn entails the consistency of the syntax. Finally, in Section 7, we draw conclusions and suggest future directions of work.

2 The Host Type Theory

We work in Martin-Löf type theory extended with functional extensionality, uniqueness of identity proofs (UIP), and sized types. Practically, we work in Agda, which supports sized types and where UIP holds by default. In this section, we give a brief overview of these principles and we introduce the basic Agda notation that we employ in our formalization.

We write \( = \) for judgmental equality and \( \equiv \) for propositional equality. Implicit arguments of functions are delimited by curly brackets. We write \( \forall \{ \Delta \} \) for an implicit argument \( \Delta \) whose type can be inferred by Agda. We write \( \text{Set}, \text{Set}_1 \) and \( \text{Set}_2 \) for the first three universes of types. We write \( \bot \) for the empty type.

We make extensive use of record types. These are like iterated \( \Sigma \)-types, in which each component, also called field, has been given a name. We open each record we introduce, which allows us to access a field by function application. For example, given a record type \( R \) containing a field \( f \) of type \( A \), we have \( f : A \). We use Agda’s copatterns for defining elements of a record type. If a record type \( R \) contains fields \( f_1 : A_1 \) and \( f_2 : A_2 \), we construct a term \( r : R \) by specifying its components \( f_1 : A_1 \) and \( f_2 : A_2 \).

The principle of functional extensionality states that every two functions \( f \) and \( g \) in the same function space are equal whenever \( f x \) and \( g x \) are equal for all inputs \( x \). This principle is not provable in Agda, so we need to postulate it. UIP states that all proofs of an identity are propositionally equal. Agda natively supports this principle, which is therefore derivable.
Agda also natively supports sized types [2, 6]. Intuitively, a sized type is a type annotated with an abstract ordinal indicating the number of possible unfoldings that can be performed of elements of the type. These abstract ordinals, called sizes, assist the termination checker in assessing the well-definedness of corecursive definitions.

In Agda, there is a type \( \text{Size} \) of sizes and a type \( \text{Size}<i \) of sizes strictly smaller than \( i \). Every size \( j : \text{Size}<i \) is coerced to \( j : \text{Size} \). The order relation on sizes is transitive, which means that whenever \( j : \text{Size}<i \) and \( k : \text{Size}<j \), then \( k : \text{Size}<i \). The order relation is also well-founded, which is used to define productive corecursive functions. There is a successor operation \( \uparrow \) on sizes and a size \( \infty \) such that \( i : \text{Size}<\infty \) for all \( i \). Lastly, we define a sized type to be a type indexed by \( \text{Size} \).

3 The Object Type Theory

The object language we consider is simply typed lambda calculus extended with additional features for programming with guarded recursive and coinductive types. We call this language \( \text{GTT} \). It is a variant of Atkey and McBride’s type system for productive coprogramming [8]. In Atkey and McBride’s calculus, all judgments are indexed by a clock context, which may contain several different clocks. They extend simply typed lambda calculus with two additional type formers: a modality \( \triangledown \) for encoding time delay into types and universal quantification over clock variables \( \forall \), which is used in combination with \( \triangledown \) to specify coinductive types. In \( \text{GTT} \), judgments are also indexed by a clock context, but in our case the latter can contain at most one clock variable \( \kappa \). The type system of \( \text{GTT} \) also includes a \( \triangledown \) modality, plus a box modality corresponding to Atkey and McBride’s quantification over the clock variable \( \kappa \).

In this section we introduce the syntax of \( \text{GTT} \) as in our Agda formalization. We give a more standard presentation of the calculus in Appendix A.

\( \text{GTT} \) is a type theory with explicit substitutions [1]. It comprises well-formed types and contexts, well-typed terms and substitutions, definitional equality of terms and of substitutions. All of them depend on a clock context. In \( \text{GTT} \), the clock context can either be empty or contain a single clock \( \kappa \).

```agda
data ClockCtx : Set where
  ⊖ : ClockCtx
  κ : ClockCtx
```

We refer to types and contexts in the empty clock context as \( \odot \)-types and \( \odot \)-contexts respectively. Similarly, \( \kappa \)-types and \( \kappa \)-contexts are types and contexts depending on \( \kappa \).

3.1 Types

The well-formed types of \( \text{GTT} \) include the unit type, products, coproducts, and function spaces. Notice that \( 1 \) is a \( \odot \)-type.

```agda
data Ty : ClockCtx → Set where
  1 : Ty ⊖
  _⊔_ : ∀ {Δ} → Ty Δ → Ty Δ → Ty Δ
  _□_ : ∀ {Δ} → Ty Δ → Ty Δ → Ty Δ
  _→_ : ∀ {Δ} → Ty Δ → Ty Δ → Ty Δ
```

We include a modality \( \triangledown \) as an operation on \( \kappa \)-types similar to the one in Atkey and McBride’s system. There also is a nameless analogue of clock quantification, which we call “box” and denote by \( \Box \) following [14]. The box modality takes a \( \kappa \)-type and returns a \( \odot \)-type.
The well-formed types of GTT include a weakening type former $\uparrow$, which maps $\emptyset$-types to $\kappa$-types.

$$
\begin{align*}
\triangleright : & \quad \text{Ty } \kappa \rightarrow \text{Ty } \kappa \\
\Box : & \quad \text{Ty } \kappa \rightarrow \text{Ty } \emptyset \\
\uparrow : & \quad \text{Ty } \emptyset \rightarrow \text{Ty } \kappa
\end{align*}
$$

Guarded recursive types are defined using a least fixpoint type former $\mu$.

$$
\mu : \forall \{\Delta\} \rightarrow \text{Code } \Delta \rightarrow \text{Ty } \Delta
$$

For $\mu$ to be well-defined, one typically limits its applicability to strictly positive functors. We instead consider a grammar $\text{Code } \Delta$ for functors, which has codes for constant functors, the identity, products, coproducts, and the later modality. Since there is a code for constant functors, the type family $\text{Code}$ needs to be defined simultaneously with $\text{Ty}$.

```plaintext
data Code : ClockCtx \rightarrow \text{Set} where
  C : \forall \{\Delta\} \rightarrow \text{Ty } \Delta \rightarrow \text{Code } \Delta
  I : \forall \{\Delta\} \rightarrow \text{Code } \Delta
  _\Box_ : \forall \{\Delta\} \rightarrow \text{Code } \Delta \rightarrow \text{Code } \Delta \rightarrow \text{Code } \Delta
  _\triangleright_ : \forall \{\Delta\} \rightarrow \text{Code } \Delta \rightarrow \text{Code } \Delta \rightarrow \text{Code } \Delta
  \triangleright : \text{Code } \emptyset \rightarrow \text{Code } \kappa
```

The constructors of $\text{Code } \Delta$ suffice for the specification of interesting examples of guarded recursive types such as streams. Nevertheless, it would not be complicated to add exponentials with constant domain and the box modality to the grammar. In addition, this grammar does not allow the possibility of defining nested inductive types.

### 3.2 Contexts

The well-formed contexts of GTT are built from the empty context, context extension, and context weakening. The last operation embeds $\emptyset$-contexts into $\kappa$-contexts. Notice that we are overloading the symbol $\uparrow$, which is used for both type and context weakening.

```plaintext
data Ctx : ClockCtx \rightarrow \text{Set} where
  • : \forall \{\Delta\} \rightarrow \text{Ctx } \Delta
  _\Box_ : \forall \{\Delta\} \rightarrow \text{Ctx } \Delta \rightarrow \text{Ty } \Delta \rightarrow \text{Ctx } \Delta
  \uparrow : \text{Ctx } \emptyset \rightarrow \text{Ctx } \kappa
```

### 3.3 Terms

The well-typed terms and substitutions of GTT are defined simultaneously. Terms include constructors for variables and substitutions.

```plaintext
data Tm : \forall \{\Delta\} \rightarrow \text{Ctx } \Delta \rightarrow \text{Ty } \Delta \rightarrow \text{Set} where
  var : \forall \{\Delta\} (\Gamma : \text{Ctx } \Delta) (A : \text{Ty } \Delta) \rightarrow \text{Tm } \Gamma (A) A
  sub : \forall \{\Delta\} (\Gamma_1 \Gamma_2 : \text{Ctx } \Delta) (A : \text{Ty } \Delta) \rightarrow \text{Tm } \Gamma_2 A \rightarrow \text{Sub } \Gamma_1 \Gamma_2 \rightarrow \text{Tm } \Gamma_1 A
```

We have lambda abstraction and application, plus the usual introduction and elimination rules for the unit types, products, coproducts, and guarded recursive types. Here we only show the typing rules associated to function types and guarded recursive types. The function
Guarded Recursion in Agda via Sized Types

\texttt{eval} evaluates codes in \texttt{Code} \(\Delta\) into endofunctors on \texttt{Ty} \(\Delta\). We use a categorical combinator \texttt{app} for application. We derive the conventional application, taking additionally an element in \texttt{Tm} \(\Gamma A\) and returning an inhabitant of \texttt{Tm} \(\Gamma B\), in Section 3.4.

\begin{align*}
\texttt{lambda} : & \forall \{\Delta\} \{\Gamma : \text{Ctx} \Delta\} \{A B : \text{Ty} \Delta\} \to \text{Tm} (\Gamma, A) B \to \text{Tm} (\Gamma, A) B \\
\texttt{app} : & \forall \{\Delta\} \{\Gamma : \text{Ctx} \Delta\} \{A B : \text{Ty} \Delta\} \to \text{Tm} (\Gamma (A \to B)) \to \text{Tm} (\Gamma (A \to B)) B \\
\texttt{cons} : & \forall \{\Delta\} \{\Gamma : \text{Ctx} \Delta\} \{P : \text{Code} \Delta\} \to \text{Tm} (\Gamma (\text{eval} (\mu P))) \to \text{Tm} (\Gamma (\mu P)) \\
\texttt{primrec} : & \forall \{\Delta\} \{\Gamma : \text{Ctx} \Delta\} \{A : \text{Ty} \Delta\} \\
& \to \text{Tm} (\Gamma (\text{eval} (\mu P (\mu P \otimes A) A)) A) \to \text{Tm} (\Gamma (\mu P A)) \\
\end{align*}

The later modality is required to be an applicative functor, which means that we have terms \texttt{next} and \texttt{@}. The delayed fixpoint combinator \texttt{dfix} \([9]\) allows defining productive recursive programs. The usual fixpoint returning a term in \(\Gamma \uparrow A\) instead of \(\Gamma \triangleright A\) is derivable.

\begin{align*}
\texttt{next} : & \{\Gamma : \text{Ctx} \kappa\} \{A : \text{Ty} \kappa\} \to \text{Tm} (\Gamma \uparrow A) \to \text{Tm} (\Gamma (\uparrow A)) \\
\texttt{@}_- : & \{\Gamma : \text{Ctx} \kappa\} \{A B : \text{Ty} \kappa\} \to \text{Tm} (\Gamma (\uparrow (A \to B))) A \to \text{Tm} (\Gamma (\uparrow (A \to B))) \to \text{Tm} (\Gamma (\uparrow B)) \\
\texttt{dfix} : & \{\Gamma : \text{Ctx} \kappa\} \{A : \text{Ty} \kappa\} \to \text{Tm} (\Gamma (\uparrow A)) \to \text{Tm} (\Gamma (\uparrow A)) A \\
\end{align*}

We have introduction and elimination rules for the \(\square\) modality. The rule \texttt{box} is the analogue in \texttt{GTT} of Atkey and McBride’s rule for clock abstraction \([8]\). Notice that \texttt{box} can only be applied to terms of type \(A\) over a weakened context \(\uparrow \Gamma\). This is analogous to Atkey and McBride’s side condition requiring the universally quantified clock variable to not appear freely in the context \(\Gamma\). Similarly, the rule \texttt{unbox} corresponds to clock application. The operation \texttt{force} is used for removing occurrences of \(\triangleright\) protected by the \(\square\) modality.

\begin{align*}
\texttt{box} : & \{\Gamma : \text{Ctx} \otimes\} \{A : \text{Ty} \kappa\} \to \text{Tm} (\uparrow \Gamma (\uparrow \Gamma \otimes A)) A \to \text{Tm} (\Gamma (\square A)) \\
\texttt{unbox} : & \{\Gamma : \text{Ctx} \otimes\} \{A : \text{Ty} \kappa\} \to \text{Tm} (\uparrow \Gamma (\square A)) \to \text{Tm} (\uparrow \Gamma (\uparrow A)) \\
\texttt{force} : & \{\Gamma : \text{Ctx} \otimes\} \{A : \text{Ty} \kappa\} \to \text{Tm} (\Gamma (\square A)) \to \text{Tm} (\Gamma (\square A)) A \\
\end{align*}

The introduction and elimination rules for type weakening say that elements of \texttt{Tm} \(\Gamma A\) can be embedded in \texttt{Tm} \(\uparrow \Gamma (\uparrow \Gamma) (\uparrow A)\) and vice versa.

\begin{align*}
\texttt{up} : & \{\Gamma : \text{Ctx} \otimes\} \{A : \text{Ty} \otimes\} \to \text{Tm} (\uparrow \Gamma A) \to \text{Tm} (\uparrow \Gamma (\uparrow A)) (\uparrow A) \\
\texttt{down} : & \{\Gamma : \text{Ctx} \otimes\} \{A : \text{Ty} \otimes\} \to \text{Tm} (\uparrow \Gamma (\uparrow A)) (\uparrow A) \to \text{Tm} (\Gamma A) \\
\end{align*}

Atkey and McBride assume the existence of certain type equalities \([8]\). Mögelberg, who works in a dependently typed setting, considers similar type isomorphisms \([20]\). In \texttt{GTT}, we follow the second approach. This means that we do not introduce an equivalence relation on types specifying which types should be considered equal, as in Chapman’s object type theory \([13]\). Instead, we include additional term constructors corresponding to functions underlying the required type isomorphisms. For example, the clock irrelevance axiom formulated in our setting states that every \(\otimes\)-type \(A\) is isomorphic to \(\square (\uparrow A)\). This is obtained by adding to \texttt{Tm} a constructor \(\square \text{const}\).

\begin{align*}
\square \text{const} : & \{\Gamma : \text{Ctx} \otimes\} \{A : \text{Ty} \otimes\} \to \text{Tm} (\Gamma (\square (\uparrow A) A)) \\
\end{align*}

A function \(\text{const} \square A\) in the other direction is derivable. When defining definitional equality on terms, described in Section 3.5, we ask for \(\square \text{const}\) and \(\text{const} \square\) to be each other inverses. The other type isomorphisms, listed in Appendix A are constructed in a similar way.
3.4 Substitutions

For substitutions, we need the canonical necessary operations [7, 13]: identity and composition of substitutions, the empty substitution, the extension with an additional term, and the projection which forgets the last term.

\[
\begin{align*}
data \text{ Sub} : & \forall \{ \Delta \} \to \text{Ctx} \Delta \to \text{Ctx} \Delta \to \text{Set} \text{ where} \\
x : & \forall \{ \Delta \} \to (\Gamma : \text{Ctx} \Delta) \to \text{Sub} \Gamma \bullet \\
\text{id} : & \forall \{ \Delta \} \to (\Gamma : \text{Ctx} \Delta) \to \text{Sub} \Gamma \Gamma \\
\_\_ : & \forall \{ \Delta \} \to (\Gamma_1 \Gamma_2 : \text{Ctx} \Delta) \to \{ A : \text{Ty} \Delta \} \to \text{Sub} \Gamma_1 \Gamma_2 \to \text{Tm} \Gamma_1 A \to \text{Sub} \Gamma_1 (\Gamma_2, A) \\
\_\_o_\_ : & \forall \{ \Delta \} \to (\Gamma_1 \Gamma_2 \Gamma_3 : \text{Ctx} \Delta) \to \text{Sub} \Gamma_2 \Gamma_3 \Gamma_1 \to \text{Sub} \Gamma_1 \Gamma_2 \to \text{Sub} \Gamma_1 \Gamma_3 \\
\text{pr} : & \forall \{ \Delta \} \to (\Gamma_1 \Gamma_2 : \text{Ctx} \Delta) \to \{ A : \text{Ty} \Delta \} \to \text{Sub} \Gamma_1 (\Gamma_2, A) \to \text{Sub} \Gamma_1 \Gamma_2 \\
\end{align*}
\]

We also add rules for embedding substitutions between \( \varnothing \)-contexts into substitutions between \( \kappa \)-contexts and vice versa.

\[
\begin{align*}
\text{up} : & \{ \Gamma_1 \Gamma_2 : \text{Ctx} \varnothing \} \to \text{Sub} \Gamma_1 \Gamma_2 \to \text{Sub} (\uparrow \Gamma_1) (\uparrow \Gamma_2) \\
\text{down} : & \{ \Gamma_1 \Gamma_2 : \text{Ctx} \varnothing \} \to \text{Sub} (\uparrow \Gamma_1) (\uparrow \Gamma_2) \to \text{Sub} \Gamma_1 \Gamma_2 \\
\end{align*}
\]

In addition, we require the existence of two context isomorphisms. The context \( \uparrow \bullet \) needs to be isomorphic to \( \bullet \) and \( \uparrow (\Gamma, A) \) needs to be isomorphic to \( \uparrow \Gamma, \uparrow A \). For both of them, we add a constructor representing the underlying functions.

\[
\begin{align*}
\bullet \uparrow : & \text{Sub} \bullet (\uparrow \bullet) \\
\uparrow & : (\Gamma : \text{Ctx} \varnothing) \to \text{Sub} \uparrow \Gamma \uparrow A (\uparrow (\Gamma, A)) \\
\end{align*}
\]

An element \( \uparrow \bullet \) in \( \text{Sub} (\uparrow \bullet) \bullet \) is derivable. In the definitional equality on substitutions, we ask for \( \bullet \uparrow \) and \( \uparrow \bullet \) to be each other inverses. We proceed similarly with \( \uparrow \).

Using the term constructor \( \text{sub} \), we can derive a weakening operation for terms and the conventional application combinator.

\[
\begin{align*}
\text{wk} : & \forall \{ \Delta \} \to (\Gamma : \text{Ctx} \Delta) \to \{ A B : \text{Ty} \Delta \} \to \text{Tm} \Gamma B \to \text{Tm} (\Gamma, A) B \\
\text{wk} \Delta : & \{ \Gamma \} \to \{ A \} x = \text{sub} x (\text{pr} (\text{id} (\Gamma, A))) \\
\_\_\$\_ : & \forall \{ \Delta \} \to (\Gamma : \text{Ctx} \Delta) \to \{ A B : \text{Ty} \Delta \} \to \text{Tm} \Gamma (A \to B) \to \text{Tm} \Gamma A \to \text{Tm} \Gamma B \\
\_\_\$\_ : & \forall \{ \Delta \} \to (\Gamma) f x = \text{sub} (\text{app} f) (\text{id} (\Gamma, x)) \\
\end{align*}
\]

3.5 Definitional equalities

Definitional equalities on terms and substitutions are defined simultaneously. Here we only discuss equality on terms and we refer to the formalization for the equality on substitutions.

\[
\begin{align*}
data \_\_\_\_ : & \forall \{ \Delta \} \to (\Gamma : \text{Ctx} \Delta) \to \{ A : \text{Ty} \Delta \} (t_1 t_2 : \text{Tm} \Gamma A) \to \text{Set} \text{ where} \\
\end{align*}
\]

The term equality includes rules for equivalence, congruence, and substitution. There also are \( \beta \) and \( \eta \) rules for the type formers. We only show the ones associated to the \( \Box \) modality here. The rules state that \( \text{box} \) and \( \text{unbox} \) are each other’s inverses.

\[
\begin{align*}
\Box \beta : & \forall \{ \Gamma \} \to \{ A \} t : \text{Tm} (\uparrow \Gamma) A \to \text{unbox} (\text{box} t) \sim t \\
\Box \eta : & \forall \{ \Gamma \} \to \{ A \} t : \text{Tm} \Gamma (\Box A) \to \text{box} (\text{unbox} t) \sim t \\
\end{align*}
\]
We include definitional equalities stating that \( \triangleright \) is an applicative functor w.r.t. the operations \( \text{next} \) and \( \psi \). Furthermore, the delayed fixpoint combinator \( \text{dfix} \) must satisfy its characteristic unfolding equation. We refer to Mogelberg’s paper [20] for a complete list of the required definitional equalities for \( \triangleright \) and \( \Box \).

For the type isomorphisms, we require term equalities exhibiting that certain maps are mutual inverses. For example, we have the following two equalities about \( \Box \text{const} \) and \( \text{const} \Box \):

\[
\text{const} \Box \text{const} : \forall \{ \Gamma \} \{ A \} (t : \text{Tm} \Gamma (\Box (\uparrow A))) \rightarrow \text{const} A \ ((\Box \text{const} A \ t) \sim t)
\]

\[
\Box \text{const} \Box \text{const} : \forall \{ \Gamma \} \{ A \} (t : \text{Tm} \Gamma A) \rightarrow \Box \text{const} A \ ((\text{const} \Box A \ t) \sim t)
\]

The last group of term equalities describes the relationship between the weakening operations \( \uparrow \) and \( \downarrow \) and other term constructors. Here we omit their description and we refer the interested reader to the Agda formalization.

### 3.6 Example: Streams

We give a taste of how to program with streams in \( \text{GTT} \). Our implementation is based on Atkey and McBride’s approach to coinductive types [8]. To define a type of streams, we first define guarded streams over a \( \emptyset \)-type \( A \). It is the least fixpoint of the functor with code \( C (\uparrow A) \otimes \triangleright I \).

\[
F : \text{Ty} \emptyset \rightarrow \text{Code} \kappa
\]

\[
F A = C (\uparrow A) \otimes \triangleright I
\]

\[
g\text{-Str} : \text{Ty} \emptyset \rightarrow \text{Ty} \kappa
\]

\[
g\text{-Str} = \mu (F A)
\]

The usual type of streams over \( A \) is then obtained by applying the \( \Box \) modality to \( g\text{-Str} A \).

\[
\text{Str} : \text{Ty} \emptyset \rightarrow \text{Ty} \emptyset
\]

\[
\text{Str} A = \Box (g\text{-Str} A)
\]

We compute the head and tail of a stream using a function \( \text{decons} \), which destructs an element of an inductive type. The term \( \text{decons} \) is the inverse of \( \text{cons} \) and it is derivable using \( \text{primrec} \). Note that in both cases we need to use \( \text{unbox} \), because of the application of the box modality in the definition of \( \text{Str} \). For the tail, we also use \( \text{box} \) and \( \text{force} \). The operations \( \pi_1 \) and \( \pi_2 \) are the projections associated to the product type former \( \otimes \).

\[
\text{hd} : \{ \Gamma : \text{Ctx} \emptyset \} \{ A : \text{Ty} \emptyset \} \rightarrow \text{Tm} \Gamma (\text{Str} A) \rightarrow \text{Tm} \Gamma A
\]

\[
\text{hd} \ xs = \downarrow (\pi_1 (\text{decons} (\text{unbox} \ xs)))
\]

\[
\text{tl} : \{ \Gamma : \text{Ctx} \emptyset \} \{ A : \text{Ty} \emptyset \} \rightarrow \text{Tm} \Gamma (\text{Str} A) \rightarrow \text{Tm} \Gamma (\text{Str} A)
\]

\[
\text{tl} \ xs = \text{force} (\text{box} (\pi_2 (\text{decons} (\text{unbox} \ xs))))
\]

Given a \( \text{GTT} \) term \( a \) of type \( A \), we can construct the constant guarded stream over \( a \) using the fixpoint combinator.

\[
g\text{-const-str} : \{ \Gamma : \text{Ctx} \emptyset \} \{ A : \text{Ty} \emptyset \} \rightarrow \text{Tm} \Gamma A \rightarrow \text{Tm} (\uparrow \Gamma) (g\text{-Str} A)
\]

\[
g\text{-const-str} \ \{ \Gamma \} \{ A \} \ a = \text{fix} (\lambda \text{cons} (F A) [ \text{wk} (\uparrow a) \ & \ \text{var} (\uparrow \Gamma) (\triangleright (g\text{-Str} A)) ])
\]

The constant stream over \( a \) is obtained by boxing the guarded stream \( g\text{-const} \ a \).
const-str : {Γ : Ctx ∅} {A : Ty ∅} → Tm Γ A → Tm Γ (Str A)
const-str a = box (g-const-str a)

In our Agda formalization, we also construct a function removing the elements at even indices out of a given stream, which is an example of a non-causal function.

4 Categorical Semantics

Next we give a categorical semantics for the calculus introduced in Section 3. We take inspiration from Møgelberg’s model [20] in which a (simple) type in a clock context containing \( n \) clocks is interpreted as a presheaf in \( \text{Set}^{\omega^n} \), where \( \omega \) is the preorder of ordered natural numbers. In our model, we replace the category \( \omega \) with the preorder of sizes. Moreover, we only consider the cases where either the clock context is empty or it contains exactly one clock. This means that a type in \( \text{GTT} \) is either interpreted as an element of \( \text{Set} \) or as a presheaf over \( \text{Size} \). In this section, we show how to implement presheaves and how to model the fragment of \( \text{GTT} \) corresponding to simply typed lambda calculus. The interpretation of the guarded recursive and coinductive features of \( \text{GTT} \) is given in Section 5.

4.1 Presheaves

Presheaves are defined as a record \( \text{PSh} \). The fields \( \text{Obj} \) and \( \text{Mor} \) represent the actions on objects and morphisms respectively, while \( \text{MorId} \) and \( \text{MorComp} \) are the functor laws. The type \( \text{Size}< (\uparrow \ i) \) contains sizes smaller or equal than \( i \). In the type of \( \text{MorId} \) we use the reflexivity of the order on sizes, which means \( i : \text{Size}< (\uparrow \ i) \). In the type of \( \text{MorComp} \) we use transitivity.

record \( \text{PSh} : \text{Set}_1 \) where
field
  field
    Obj : Size → Set
    Mor : {i : Size} {j : Size< (\uparrow \ j)} → Obj i → Obj j
    MorId : {i : Size} {x : Obj i} → Mor i i x ≡ x
    MorComp : {i : Size} {j : Size< (\uparrow \ j)} {k : Size< (\uparrow \ j)} {x : Obj i}
              → Mor i k x ≡ Mor j k (Mor i j x)

Beside presheaves, we also need natural transformations. These are defined as a record \( \text{NatTrans} \), consisting of a map \( \text{nat-map} \) and a proof of the usual commutativity requirement.

record \( \text{NatTrans} (P Q : \text{PSh}) : \text{Set} \) where
field
  field
    nat-map : {i : Size} → Obj P i → Obj Q i
    nat-com : {i : Size} {j : Size< (\uparrow \ j)} {x : Obj P i}
             → Mor Q i j (nat-map i x) ≡ nat-map j (Mor P i j x)

Products and sums of presheaves are defined pointwise. More precisely, we define the product as follows.

\[ \text{ProdObj} : \text{Size} → \text{Set} \]
\[ \text{ProdObj} \ i = \text{Obj} P \ i × \text{Obj} Q \ i \]

The sum is defined similarly. The weakening type former \( \uparrow \) of \( \text{GTT} \) is modeled using the constant presheaf, which we denote by \( \text{Const} \). Function spaces are defined as the exponential of presheaves. The action on a size \( i \) of this presheaf consists of natural transformations restricted to sizes smaller or equal than \( i \).
record ExpObj (P Q : PSh) (i : Size) : Set where
  field
  fun : (j : Size< (↑i)) → Obj P j → Obj Q j
  funcom : (j : Size< (↑i)) (k : Size< (↑j)) (x : Obj P j)
           → Mor Q j k (fun j x) ≡ fun k (Mor P j k x)

All in all, we get an operation \( \text{Exp} : \text{PSh} \to \text{PSh} \to \text{PSh} \).

4.2 Modelling Simple Types

To interpret the fragment of \( \text{GTT} \) corresponding to simply typed lambda calculus, we use Kripke semantics [18]. Semantic judgments, similar to their syntactic counterparts, are indexed by a clock context. We reuse the type \( \text{ClockCtx} \) for the semantic clock contexts. The semantic variable contexts are sets if the clock context is empty, and they are presheaves otherwise.

\[
\begin{align*}
\text{SemCtx} &: \text{ClockCtx} \to \text{Set}, \\
\text{SemCtx} \emptyset &= \text{Set} \\
\text{SemCtx} \kappa &= \text{PSh}
\end{align*}
\]

Note that \( \text{GTT} \) is a simple type theory, thus types do not depend on contexts. For this reason, we define the type \( \text{SemTy} \) of semantic types in the same way as \( \text{SemCtx} \).

The semantic terms of type \( A \) in context \( \Gamma \) are functions from \( \Gamma \) to \( A \) if the clock context is empty, and they are natural transformations between \( \Gamma \) and \( A \) otherwise.

\[
\begin{align*}
\text{SemTm} &: \forall \Delta : \text{ClockCtx} \to \text{Set} \\
\text{SemTm} \emptyset \Gamma A &= \Gamma \to A \\
\text{SemTm} \kappa \Gamma A &= \text{NatTrans} \Gamma A
\end{align*}
\]

Since \( \text{GTT} \) is a type theory with explicit substitutions, we must provide an interpretation for them as well. Semantic substitutions are maps between contexts and we define the type \( \text{SemSub} \) in the same way as \( \text{SemTm} \). Definitional equality of semantic terms and substitutions is modeled as propositional equality.

We also need to provide a semantic version of the context operations, the simple type formers and the operations on substitutions. Since their definitions are standard, we do not discuss them in detail. For each of them, we need to make a case distinction based on the clock context. For example, the empty variable context \( \bullet \) is interpreted as the unit type in the clock context \( \emptyset \), and it is interpreted as the terminal presheaf in the clock context \( \kappa \). We use the operations on presheaves defined in Section 4.1 to interpret simple type formers. In the next section, we use the interpretation of function types, whose action of objects in the clock context \( \kappa \) is given by \( \text{ExpObj} \). This is denoted by \( A \Rightarrow B \) for semantic types \( A \) and \( B \).

\[
\begin{align*}
\Rightarrow &: \forall \Delta : \text{SemTy} \Delta \to \text{SemTy} \\
\Rightarrow &\emptyset (A B : \Delta) \to \Delta \\
\Rightarrow &\emptyset (A B : \text{Set}) \to A \to B \\
\Rightarrow &\kappa (A B : \text{Exp}) \to A \to B
\end{align*}
\]

5 Modelling Guarded Recursion

In this section, we add the required guarded recursive and coinductive features to the denotational semantics. We start by defining the semantic box modality together with its introduction and elimination rule. Then we construct the semantic later modality. We show how to define the fixpoint combinator and the force operation using sized types. In the end, we discuss how to model guarded recursive types.
5.1 Context Weakening and the Box Modality

Similarly to the weakening type former $\uparrow$, the weakening context former $\uparrow \Gamma$ is modeled using the constant presheaf $\text{Const}$. 

$\uparrow : \text{SemCtx} \varnothing \to \text{SemCtx} \kappa$

$\uparrow \Gamma \equiv \text{Const} \Gamma$

Møgelberg models universal clock quantification by taking limits [20]. We define the semantic box modality $\blacksquare$ similarly: given a presheaf $A$, we take $\blacksquare A$ to be the limit of $A$.

Formally, the limit of $A$ is constructed as a record with two fields. The field $\blacksquare \text{cone}$ is given by a family $f_i$ in $\text{Obj} A_i$ for each size $i$. The field $\blacksquare \text{com}$ is a proof that the restriction of $f_i$ to a size $j$ smaller than $i$ is equal to $f_j$.

$$
\text{record} \quad \blacksquare (A : \text{SemTy} \kappa) : \text{SemTy} \varnothing \quad \text{where}
\begin{align*}
\blacksquare \text{cone} : (i : \text{Size}) \to \text{Obj} A i \\
\blacksquare \text{com} : (i : \text{Size}) (j : \text{Size} < (\uparrow i)) \to \text{Mor} A i j (\blacksquare \text{cone} i) \equiv \blacksquare \text{cone} j
\end{align*}
$$

The semantic box modality is right adjoint to context weakening. In other words, the types $\text{Tm}(\uparrow \Gamma) A$ and $\text{Tm} \Gamma (\blacksquare A)$ are isomorphic for all $\Gamma$ and $A$. The function underlying the isomorphism is $\text{sem-box}$ and its inverse is $\text{sem-unbox}$, modeling $\text{box}$ and $\text{unbox}$ respectively.

$$
\text{sem-box} : (\Gamma : \text{SemCtx} \varnothing) (A : \text{SemTy} \kappa) (t : \text{SemTm}(\uparrow \Gamma) A) \to \text{SemTm} \Gamma (\blacksquare A)
\begin{align*}
\text{nat-map} (\text{sem-box} \Gamma A t x i) & = \text{nat-map} t i x \\
\text{nat-com} (\text{sem-box} \Gamma A t x i j) & = \text{nat-com} t i j x
\end{align*}
$$

$$
\text{sem-unbox} : (\Gamma : \text{SemCtx} \varnothing) (A : \text{SemTy} \kappa) (t : \text{SemTm} \Gamma (\blacksquare A)) \to \text{SemTm}(\uparrow \Gamma) A
\begin{align*}
\text{nat-map} (\text{sem-unbox} \Gamma A t l i x) & = \blacksquare \text{cone} (t x) i \\
\text{nat-com} (\text{sem-unbox} \Gamma A t l i j x) & = \blacksquare \text{com} (t x) i j
\end{align*}
$$

5.2 The Later Modality

The semantic later modality is an operation $\triangleright$ on semantic $\kappa$-types. Recall that the later modality in the topos of trees [11] is defined as

$$(\triangleright A)(0) = \{\ast\}$$

$$(\triangleright A)(n + 1) = A(n)$$

We cannot directly replicate the latter in our setting since the preorder of sizes does not possess a least element. However, we know from [11] that the definition above is equivalent to $$(\triangleright A)(n) = \text{lim}_{k<n} A(k)$$. Adapting this to our setting leads to the following action of $\triangleright$ on objects:

$$
\text{record} \quad \triangleright \text{ObjTry} (A : \text{SemTy} \kappa) (i : \text{Size}) : \text{Set} \quad \text{where}
\begin{align*}
\triangleright \text{cone} : (j : \text{Size} < i) \to \text{Obj} A j \\
\triangleright \text{com} : (j : \text{Size} < i) (k : \text{Size} < (\uparrow j)) \to \text{Mor} A j k (\triangleright \text{cone} j) \equiv \triangleright \text{cone} k
\end{align*}
$$

However, with this definition, we are unable to implement a terminating semantic fixpoint combinator. Later in this section we discuss why this is the case.
There are several ways to modify the above definition and implement a terminating fixpoint operation. A possible solution, which was suggested to us by Andrea Vezzosi, is using an inductive analogue of the predicate $\text{Size}<$, which we call $\text{SizeLt}$.

```agda
data SizeLt (i : Size) : Set where
[ ] : Size< i → SizeLt i
```

The type $\text{SizeLt}$ is a mechanism for suspending computations. If we define a function $f$ of type $(j : \text{SizeLt} i) \rightarrow \text{Obj} A j$ by pattern matching, then $f j$ does not reduce unless $j$ is of the form $[j']$ for some $j' : \text{Size}< i$. This simple observation turns out to be essential for a terminating implementation of the fixpoint combinator.

From an inhabitant of $\text{SizeLt}$, we obtain an actual size by pattern matching.

```agda
size : ∀ {i} → SizeLt i → Size
size [j] = j
```

Furthermore, functions with domain $\text{SizeLt} i$ can be specified using functions on $\text{Size}< i$.

```agda
elimLt : (A : Size → Set) {i} → (j : Size< i) → A j
→ (j : SizeLt i) → A (size j)
elimLt f [j] = f j
```

We define the action on objects of the semantic later modality similarly to $\text{ObjTry}$ but with $\text{SizeLt}$ in place of $\text{Size}<$. Before we do so, we introduce two auxiliary functions, which turn out to be handy when modeling guarded recursive types. The first is a function $\text{Later}$, which instead of a semantic $\kappa$-type, takes a sized type as its input. Its definition is the same as the type of the field $\text{ cone}$ in $\text{ObjTry}$ but with $\text{Size}< i$ replaced by $\text{SizeLt}$.

```agda
Later : (Size → Set) → Size → Set
Later A i = (j : SizeLt i) → A (size j)
```

The second auxiliary function is $\text{LaterLim}$. It takes as input a sized type $A$ together with a proof that it is antitone. Again its definition is the same as the type of the field $\text{ com}$ in $\text{ObjTry}$ but with $\text{Size}< i$ replaced by $\text{SizeLt}$.

```agda
LaterLim : (A : Size → Set) (m : (i : Size) (j : Size< (↑ i)) → A i → A j)
→ (i : Size) (x : Later A i) → Set
LaterLim A m i x = (j : SizeLt i)
→ elimLt (λ { j' → (k : SizeLt (↑ j'))} (λ k' → m j' k' (x [j']) ≡ x [k'] k)) j
```

Putting everything together, we obtain the following definition of the object part of the semantic later modality $\triangleright$. We refer to the Agda formalization for the action on the morphisms and the functor laws.

```agda
record $\triangleright$ (A : SemTy κ) (i : Size) : Set where
field
$\triangleright$cone : Later (Obj A) i
$\triangleright$com : LaterLim (Obj A) (Mor A) i $\triangleright$cone
```

We omit the semantic equivalents of $\text{next}$ and $\bowtie$. To interpret the delayed fixpoint combinator $\text{dfix}$, we introduce an auxiliary term $\text{sem-dfix}_1$, for which we only show how to construct the field $\text{ cone}$. This is defined using self-application.
This definition is accepted by Agda’s termination checker for two reasons:
- every recursive call is applied to a strictly smaller size;
- the usage of `SizeLt` in place of `Size<` in the definition of `Later` prevents indefinite unfolding,
  which would have happened if we used `ObjTry` instead of `Obj`.

In fact, if we would replace `Obj` by `ObjTry` as the return type of `sem-dfix` while keeping
the same definition (with `j` in place of `[j]`), we would obtain the following non-terminating
sequence of reductions:

\[ \downarrow \text{cone} (\text{sem-dfix} \ A i f) \downarrow = \lambda j \to \text{fun} f j (\text{sem-dfix} \ A j f) \]
\[ \downarrow \text{cone} (\text{sem-dfix} \ A i f) \downarrow = \lambda j \to \text{fun} f j (\text{record} \{ \downarrow \text{cone} = \lambda k \to \text{fun} f k (\text{sem-dfix} \ A k f) \; ; \downarrow \text{com} = \ldots \}) \]
\[ = \ldots \]

The termination of the `\downarrow \text{com}` component of `sem-dfix` additionally relies on the presence
of `elimLt` in the definition of `LaterLim`.

The field `nat-map` of `sem-dfix` is defined using `sem-dfix`. We omit the `nat-com` component.

Finally, we show how to interpret `force`. To this aim, we introduce an auxiliary function `sem-force'`, which, given a type `A` and an inhabitant `t` of `\downarrow (\downarrow A)`, returns a term in `\downarrow A`. For
the field `\downarrow \text{cone}` of `sem-force' A t`, we are required to construct an element of `Obj A i` for
each size `i`. Notice that `\downarrow \text{cone} t`, when applied to a size `i`, gives a term `t'` of type `\downarrow \text{Obj} A i'`.
Furthermore, the component `\downarrow \text{cone}` of `t'`, when applied to a size `j` smaller than `i'`, returns a
term of type `Obj A j'`. Hence, in order to construct the required inhabitant of `Obj A i`, it
suffices to find a size `j` greater than `i`. An option for such a size `j` is `*`. The field `\downarrow \text{com}` is
defined in a similar way.

Finally, the semantic force operation follows immediately from `sem-force'`.

\[ \text{sem-force} : (\Gamma : \text{SemCtx} \kappa) \ (A : \text{SemTy} \kappa) (t : \text{SemTm} \Gamma (\downarrow A)) \to \text{SemTm} \Gamma (\downarrow A) \]
\[ \text{sem-force} \ \Gamma A t x = \text{sem-force'} A (t x) \]

### 5.3 Guarded Recursive Types

For semantic guarded recursive types, we introduce a type of semantic codes for functors. We
cannot reutilize the syntactic grammar `Code` since the code for the constant functor should
depend on `SemTy` rather than `Ty`. Instead we use the following definition.

\[ \text{data SemCode} : \text{ClockCtx} \to \text{Set}_1 \text{ where} \]
\[ \ C : \forall \{\Delta\} \to \text{SemTy} \Delta \to \text{SemCode} \Delta \]
\[ \ l : \forall \{\Delta\} \to \text{SemCode} \Delta \]
In the remainder of this section, we only discuss guarded recursive \( \kappa \)-types. The interpretation of \( \mu \) in the clock context \( \varnothing \) is standard and therefore omitted. Given a semantic code \( P \), our goal is to construct the action on objects and morphisms of a presheaf \( \mu_\kappa P \).

A first naïve attempt would be to define the action on objects \( \muObj P \) as the initial algebra of \( \text{sem-eval} P \), where \( \text{sem-eval} \) evaluates a code as an endofunctor on \( \text{SemTy} \). This means defining \( \muObj P \) as an inductive type with one constructor taking in input \( \text{sem-eval} P \) (\( \muObj P \)). This idea does not work, since \( \muObj P \) is a sized type while \( \text{sem-eval} P \) expects a semantic \( \kappa \)-type.

Another possibility would be to define \( \muObj P \) by induction on \( P \). However, there is a problem when we arrive at the \( \mathbf{1} \) constructor. In this case, we would like to make a recursive call to \( \muObj \) applied to the original code \( P \), which is unavailable at this point. We solve the issue by introducing an auxiliary inductive type family \( \muObj' \), which depends on two codes instead of one. The first code is the original one used to define the guarded recursive type and we do induction on the second one. Then we define \( \muObj P \) to be \( \muObj' P P \).

The constructors of \( \muObj' P Q \) follow the structure of \( Q \). If \( Q \) is a product we have \( \muObj' \) as the product of \( \muObj' P P \) and \( \muObj' P Q \). If \( Q \) is a sum we have the two injections. When \( Q \) is a product we have a product. When \( Q \) is a sum we have the two injections. When \( Q \) is a product we have a product.

We define \( \muMor' \) to be \( \muMor' P P \). Since \( \muMor \) preserves the identity and composition, we get a presheaf \( \mu_\kappa P \) for each \( P \). This is used to interpret \( \mu \) in the clock context \( \kappa \). We write \( \mathbf{mu} \) for the interpretation of \( \mu \) in a general clock context.
6 Soundness and Consistency

We now define the notion of interpretation of GTT. To interpret types, one must give a type of semantical types and a function mapping each syntactic type to its semantical counterpart. Similarly for contexts, terms, substitutions and definitional equalities. This leads to the following record where we only show the fields related to types.

```agda
record interpret-syntax : Set₂ where
  field
  semTy : ClockCtx → Set₁
  _[__]Ty : ∀ {Δ} → Ty Δ → semTy Δ
```

Now we prove GTT sound w.r.t. the categorical semantics. We only show the interpretation of the types whose semantics were explicitly discussed in Sections 4 and 5. Since syntactic types are defined mutually with codes, the interpretation of types \([__]_{\text{type}}\) has to be defined simultaneously with the interpretation of codes \([__]_{\text{code}}\), which we omit here.

\[
\begin{align*}
  \_[\_]_{\text{type}} & : \forall \{\Delta\} \to Ty \Delta \to SemTy \Delta \\
  \_A \to B \_ & = \_A \_ \to \_B \_ \text{type} \\
  \_\Box A \_ & = \Box \_A \_ \text{type} \\
  \_\mu P \_ & = \mu \_P \_ \text{code}
\end{align*}
\]

Similarly, Ctx, Tm and Sub are mapped into SemCtx, SemTm and SemSub respectively. Definitional equality of terms is interpreted as Agda’s propositional equality, the same for definitional equality of substitutions.

```agda
sem : interpret-syntax
semTy sem = SemTy
_[__]Ty sem = [__]_{\text{type}}
```

Using the interpretation \(\text{sem}\), we can show that GTT is consistent, by which we mean that not every definitional equality is deducible. We first define a type \(\text{bool} : Ty \emptyset \equiv 1 \oplus 1\) and two terms TRUE and FALSE as \(\text{in}_1 \_tt\) and \(\text{in}_2 \_tt\) respectively, where \(\text{in}_1\) and \(\text{in}_2\) are the two constructors of \(\oplus\). We say that GTT is consistent if TRUE and FALSE are not definitionally equal.

```agda
consistent : Set
consistent = TRUE ~ FALSE → ⊥
```

This is proved by noticing that if TRUE were definitionally equal to FALSE, then their interpretations in \(\text{sem}\) would be equal. However, they are interpreted as \(\text{in}_1 \_tt\) and \(\text{in}_2 \_tt\) respectively, and those are unequal. Hence, GTT is consistent.

7 Conclusions and Future Work

We presented a simple type theory for guarded recursion that we called GTT. We formalized its syntax and semantics in Agda. Sized types were employed to interpret the characteristic features of guarded recursion. From this, we conclude that guarded recursion can be simulated using sized types. We greatly benefited from the fact that sized types constitute a native feature of Agda, so we were able to fully develop our theory inside a proof assistant.
This work can be extended in several different directions. Various type theories for guarded recursion in the literature include dependent types. Currently, there exist two disciplines for mixing dependent types with guarded recursion: delayed substitutions [12] and ticks [9]. It would be interesting to extend the syntax and semantics of \textit{GTT} with dependent types following one of these two methods.

Abel and Vezzosi [5] formalized a simple type theory extended with the later modality in Agda. They focus on operational properties of the calculus and give a certified proof of strong normalization. As future work, we plan to investigate the metatheory and the dynamic behavior of \textit{GTT} by formalizing a type checker and a normalization algorithm. This would also set up the basis for a usable implementation of \textit{GTT}.

In \textit{GTT} we restrict the least fixpoint operator $\mu$ to act exclusively on strictly positive functors. This restriction is already present in Atkey and McBride’s calculus, which is aimed at encoding coinductive types using the later modality and it does not allow solving general guarded recursive domain equations. \textit{GTT} is a variant of Atkey and McBride’s type theory, therefore the similar restriction to strictly positive functors. From the formalization perspective, this restriction allows us to use Agda’s inductive types to model the guarded recursive types of \textit{GTT}, as shown in Section 5.3. In future work, we plan to extend \textit{GTT} with the possibility of solving general guarded recursive domain equations. This could be done in two ways: extending the language with a universe, which allows the encoding of guarded recursive types as fixpoints in the universe as shown e.g. by Mogelberg [20]; or considering a $\mu$ type former which, besides strictly positive functors, also operates on functors where all variables are guarded by an occurrence of the later modality. In the second option we have to consider strictly positive functors to encode usual inductive types, such as the natural numbers.

Finally, we would like to understand whether sized types can be simulated using guarded recursion. This could either be done by modeling sized types in a topos of trees-like category [11, 19] or via the encoding of a type theory with sized types into a dependent type theory for guarded recursion such as Clocked Type Theory [9].

\begin{array}{c}
\vdash \Delta \text{ s : } \Gamma_1 \rightarrow \Gamma_2 \\
\vdash \Delta \text{ up s : } \uparrow \Gamma_1 \rightarrow \uparrow \Gamma_2 \\
\vdash \Delta \text{ down s : } \Gamma_1 \rightarrow \Gamma_2 \\
\end{array}
\]
Terms

\[
\begin{align*}
\Gamma, x : A & \vdash t : B & & \Gamma \vdash f : A \to B & & \Gamma \vdash t : A \\
\Gamma \vdash \lambda x. t : A \to B & & \Gamma \vdash \text{unitrec } t : A \\
\Gamma \vdash \text{in1 } t : A + B & & \Gamma \vdash \text{in2 } t : A + B \\
\Gamma \vdash t_1 : A & & \Gamma \vdash t_2 : B & & \Gamma, x : A \vdash t_1 : C & & \Gamma, y : B \vdash t_2 : C \\
\Gamma \vdash (t_1, t_2) : A \times B & & \Gamma \vdash \uparrow t : A & & \Gamma \vdash t : \square A & & \Gamma \vdash \uparrow t : \uparrow A & & \Gamma \vdash \downarrow t : A \\
\Gamma \vdash t : A & & \Gamma \vdash f \circ t : \uparrow A & & \Gamma \vdash f : \uparrow (A \to B) & & \Gamma \vdash \text{force } t : \square A \\
\Gamma \vdash t : \square \uparrow A & & \Gamma \vdash \text{fix } f : \square A & & \Gamma \vdash \text{primrec } f : \mu P & & \Gamma \vdash \text{eval } P : \mu P \times A \\
\end{align*}
\]

where \( F_P \) is the evaluation of the code \( P \) into endofunctors on types, called \texttt{eval} \( P \) in Section 3. We omit the presentation of the definitional equalities of terms and substitutions, which can be found in our Agda formalization.

Type Isomorphisms

\[
\square (\uparrow A) \cong A \quad \square (A + B) \cong \square A + \square B \quad \uparrow (A \to B) \cong \uparrow A \to \uparrow B \quad \uparrow (\mu P) \cong \mu (\uparrow P)
\]

Context Isomorphisms

\[
\diamond \cong \uparrow \quad \uparrow \Gamma, \uparrow A \cong \uparrow (\Gamma, A)
\]
